1 Question 6.1

1.1 Question

Using the Wikipedia collection provided at the book website, create a sample of stem clusters by the following process:

1. Index the collection without stemming.
2. Identify the first 1,000 words (in alphabetical order) in the index.
3. Create stem classes by stemming these 1,000 words and recording which words become the same stem.
4. Compute association measures (Dice's coefficient) between all pairs of stems in each stem class. Compute co-occurrence at the document level.
5. Create stem clusters by thresholding the association measure. All terms that are still connected to each other form the clusters.

Compare the stem clusters to the stem classes in terms of size and the quality (in your opinion) of the groupings.

1.2 Approach

The `stem.py` script, found in Listing 2, was used to solve this problem.

2 Question 6.2

2.1 Question

Create a simple spelling corrector based on the noisy channel model. Use a single-word language model, and an error model where all errors with the same edit distance have the same probability. Only consider edit distances of 1 or 2. Implement your own edit distance calculator (example code can easily be found on the Web)

2.2 Approach

Peter Norvig's noisy channel spelling correction algorithm [1] was used as the basis for this solution. The `spelling.py` script, found in Listing 3, was created as an implementation of this algorithm. It was written with the Python programming language [2].

A large text file was downloaded from Mr. Norvig's website to calculate language model probability function $P(W)$. The words in the text file were counted and stored in a map that was compressed and saved on disk using the pickle python library [3].

$P(W)$ is calculated with the following formula:

$$P(W) = \frac{C_W}{N}$$

where C_W is the word count for word W and N is the sum of all word counts.

The process of determining a spelling correction is as follows:

1. Take the input word and determine all existing (correctly spelled) words with edit distance one and two.
2. With the assumption that shorter edit distances equate to a higher probability of being the correct intended word, select from the set of words from the previous step the one with the shortest edit distance and highest value for $P(W)$.

2.3 Results

Here is some sample output from the `spelling.py` script.

```
1 [mchaney@mchaney-1 spelling]$ ./spelling splling
2 selling
3 [mchaney@mchaney-1 spelling]$ ./spelling sweling
4 swelling
5 [mchaney@mchaney-1 spelling]$ ./spelling aacck

3 Question 6.3

3.1 Question

Implement a simple pseudo-relevance feedback algorithm for the Galago search engine. Provide examples of the query expansions that your algorithm does, and summarize the problems and successes of your approach.

3.2 Approach

Here's a formula.

$$\frac{n_{ab}}{n_a + n_b}$$

4 Question 6.5

4.1 Question

Describe the snippet generation algorithm in Galago. Would this algorithm work well for pages with little text content? Describe in detail how you would modify the algorithm to improve it.

4.2 Answer

Snippet creation is done by the `SnippetGenerator` class. This class takes as parameters to its `getSnippet` method the document text as a `String` and a `Set` of `String` query terms, and returns a `String` that is a query-relevant snippet, or summary, of the document.

The snippet generator begins by turning the document text into a list of tokens for processing. The generator then parses these tokens, looking for query term matches, and when it finds a match, it creates a `SnippetRegion` object that stores the location within the document where the query term matched, plus five contextual terms preceding and following each term match. This equates to storing sentence fragments containing query terms.

After collecting all of the regions in the document containing a query term the generator begins constructing the final snippet by adding the `SnippetRegions` found from the previous step, combining those regions that overlap each other into larger regions, until a final list of `SnippetRegions` is created with total length in terms is no greater than $40 + \text{the length of the last } \text{SnippetRegion} \text{ added}$.

With the final list of `SnippetRegions` the algorithm builds an HTML string containing all the snippets concatenated together for rendering the snippet in a browser while adding `` tags around each query term match for emphasis.

This approach favors regions at the beginning of the document without regard to query context. One way to improve upon this method is to favor regions that contain more query terms. This can be done by counting the number of query terms found in the combined regions and then ordering the snippet generation based on the regions with the highest contained query term counts. This method could cut down the size of the final snippet by choosing regions that contain more query words within the normal extent of 5 terms per query word match, which would allow for a more concise summary of the website as it relates to the user query.

5 Question MLN2

5.1 Question

Using the small wikipedia example, choose 10 words and compute MIM, EMIM, chi square, dice association measures for full document & 5 word windows (cf. pp. 203-205)

5.2 Approach

The python script `calc.py`, found in Listing 4, was used to complete this task.

5.3 Results

Here is the output from running the `calc.py` script:

running			
<i>MIM</i>	<i>EMIM</i>	χ^2	<i>Dice</i>
Tootie	Tootie	long	ran
Mortes	Mortes	only	long
Mortem	Mortem	but	could
Alsab	Alsab	over	run
Titulus	Titulus	two	started
Cruguet	Cruguet	could	ever
defensed	defensed	had	changed
Vipiteno	Vipiteno	time	old
Velocisaurus	Velocisaurus	In	opening
Pedophilia	Pedophilia	into	end

Table 1: Calculated values for “running”

calculation			
<i>MIM</i>	<i>EMIM</i>	χ^2	<i>Dice</i>
